certifies that this is the approved version of the following dissertation:

**INVESTIGATION OF THERAPY IMPROVEMENT USING
REAL-TIME PHOTOACOUSTIC IMAGING GUIDED
HIGH INTENSITY FOCUSED ULTRASOUND**

Chairperson Dr. Xinmai Yang

Date Approved: 09/26/2012

Abstract

There are a lot of risks in cancer treatment by invasive surgery, such as bleeding, wound infection, and long recovery time, etc. Therefore, there is great need for minimally- or non-invasive treatment. High intensity focused ultrasound (HIFU) is a rapidly growing and truly non-invasive technology. It has been widely used in therapeutic applications, such as rapid tissue heating and tissue ablation. With proper imaging guidance, HIFU treatment can be performed totally noninvasively. Currently, ultrasound imaging-guided HIFU has been extensively studied. However, ultrasound imaging guidance is less precise because of the relatively low imaging contrast, sensitivity, and specificity for noninvasive detection. In this study, we employed photoacoustic imaging (PAI) technique, which has been developed a novel promising imaging technique for early cancer detection, to guide HIFU treatment. The goal of this study is to investigate the feasibility of PAI to guide, monitor in real time and enhance the HIFU therapy.

In this dissertation, as the first step, the integrated PAI and HIFU system had been shown to have the feasibility to guide HIFU both *ex vivo* and *in vivo*. Then, the system was improved and developed to a real-time PAI-guided HIFU system. It is demonstrated that the sensitivity of PA detection for HIFU lesion is very high and the saturation of PA signals can be used as the indicator for tissue coagulation. During the temperature measurement using this system, laser-enhanced HIFU heating was found. Thus, we further investigated the laser enhanced technique in both HIFU heating and pulsed HIFU thrombolysis. In the HIFU therapy, laser light was employed to illuminate the sample concurrently with HIFU radiation. The resulting cavitation was detected with a passive

cavitation detector. We demonstrated that concurrent light illumination during HIFU has the potential to significantly enhance HIFU by reducing cavitation threshold.

Acknowledgements

I would like to express my sincerely thanks to all those who gave me the possibility to complete this dissertation.

First, I wish to express my deepest gratitude to my advisor, Dr. Xinmai Yang, for his excellent and patient guidance throughout my four years graduate study and research. When I just arrived at the University of Kansas and struggled with integrating into a foreign country and lack of necessary expertise, Dr. Yang's support and encouragement gave me the strength to continue and help me make achievement today. I will never forget his words which he told me more than once to encourage me to independently think about the research I was doing but not to be satisfied as an experimentalist or technician. Dr. Yang and his family are going through a tough time recently, I want to give my best wishes to him and his family and hopefully everything will get better soon.

I would like to thank my committee members: Dr. Larry Cook, Dr. M. Laird Forrest, Dr. Carl W. Luchies and Dr. Mihai Popescu. Their comments and suggestions in my proposal defense are critical and constructive. I would never finish my dissertation without their guidance. A special thank is given to Dr. Paulette Spencer, who is the director of BioEngineering Research Center (BERC) and provides us with an excellent atmosphere for doing research.

I would like to thank Janggun Jo, Jacob Staley and Behrouz Soroushian, who are my current and former co-workers and also good friends. They were always willing to help and give their best suggestions. Many thanks to Dr. Anil Misra, Dr. Charles Ye, Dr.

Shiping Huang, Rananathan Parthasarathy, Viraj Singh and other colleagues in BERC. It would have been a lonely lab without them.

I would also like to thank my parents, grandparents, uncle and parents-in-law who always support and encourage me with their best wishes unreservedly.

Finally, I would like to thank my wife Ti Zhang for her unwavering love, considerate care and companionship. I am so blissful to share these wonderful four years with her, no matter good times or bad.

Chapter 1 Introduction

1.1 Background and motivation

High intensity focused ultrasound (HIFU) has been served as a truly non-invasive tool to treat solid tumors[1-9]. During HIFU, high intensity ultrasound is delivered and deposits a certain amount of energy to a target. The induced rapid local temperature rise, which is called hyperthermia or thermal ablation, leads to the irreversible tissue coagulation and cell death. Since HIFU technique was first introduced by Lynn et al.[10] in 1942, it has been performed in a growing number of clinical studies on several benign and malignant tumors (prostate, breast, uterine, liver, kidney, pancreas, bone, and brain)[9, 11-22].

In the last decade, HIFU have made remarkable achievements in the clinical studies with the advent of modern imaging modalities such as ultrasound (US) imaging and magnetic resonance imaging (MRI), which can provide accurate therapy guidance.

Currently, more than 90% of HIFU is performed with ultrasound guidance. Although ultrasound imaging is inexpensive and can be performed in real time, it has relatively low imaging contrast, sensitivity, and specificity for noninvasive detection[23-25], which cause loss of guidance accuracy. In addition, temperature rise during HIFU cannot yet be accurately measured with ultrasound, although efforts have been made[26-30]. Magnetic resonance imaging (MRI) is a more viable imaging technique to guide HIFU therapy because it can produce temperature images[31-36]. However, MRI makes the treatment expensive and slow. In addition, the patient must remain still in a magnet

bore, which may be a problem for claustrophobic patients. In some MRI modes (such as head and neck imaging), special RF coils are used to fit closely to the patient's anatomy, and these coils will interfere with HIFU transducer placement.

Photoacoustic imaging, also called optoacoustic imaging or thermoacoustic imaging, has been developed as a novel promising imaging technique for early cancer detection[37-44]. It is a hybrid technique that can image the distribution of optical absorption deep inside the tissue based on the photoacoustic effect. When short-pulsed laser beams irradiate on the biological tissues, the ultrasonic waves are generated due to pressure rise through transient thermoelastic expansion. The ultrasonic waves, referred as photoacoustic waves, can be detected by an ultrasonic transducer and then converted to electrical signal that can be collected by PC to analyze or form PA images. PAI overcomes the limitations of ultrasound imaging modalities and combines optical contrast with ultrasonic resolution. PAI has demonstrated imaging depth more than 5 cm[45] with the imaging resolution (from 2 μm to 500 μm) scalable to the imaging depth[42, 46]. Additionally, PAI has the advantages of being inexpensive and portable. It is demonstrated that PAI has the capability to provide guidance for HIFU treatment on solid tumors and monitor thermal lesions generated by HIFU or other means[47-50].

While HIFU therapy technique with proper imaging modalities is developing rapidly, its application is also expanding, e.g. large tumor treatment. It requires larger amount of energy deposited in the tumor region, which can be fulfilled by enhancing the local ultrasound absorption and ultrasound intensity. Increasing the HIFU intensity is one of the simple solutions. However, high power output will induce severe skin burns and

also present a great challenge for the design of HIFU system, including the design of transducer and the electronic circuits. An alternative way to avoid very high ultrasound intensity in large tumor treatment is to increase the local ultrasound absorption so that more ultrasound energy can be deposited in the local region at a relatively low HIFU intensity level. As a result, enhanced HIFU heating would be achieved at a relatively low HIFU intensity level, and side effects such as skin burns would be avoided. To enhance HIFU heating, acoustic cavitation has been investigated[51, 52] to have the capacity to increase the local ultrasound absorption and thus enhance heating.

The use of pulsed HIFU to potentiate thrombolysis is another important application of HIFU. Catheter-based ultrasound has been extensively studied as an efficient method to treat deep venous thrombosis (DVT) clinically[53-59]. During the treatment, the catheter is placed inside the blood clot and dissolves the clot through oscillating wires at high frequency and high intensity. However, catheter-based ultrasound is an invasive way to treat thrombus. The non-invasive methods are necessary to avoid bleeding, wound infection, and long recovery time. Therefore, HIFU technique has the potential for thrombolysis treatment. When using HIFU to dissolve the blood clot, the clot disruption are mainly due to cavitation effect[54, 57, 60-62]. However, using pulsed HIFU treatment alone are limited and have a relatively low thrombolysis efficiency[63, 64].

As we mentioned, in HIFU applications, acoustic cavitation plays a vital role in both HIFU ablation and pulsed HIFU thrombolysis. When cavitation occurs, collapse (stable cavitation) and pulsate violently (inertial cavitation) can damage nearby structures

without heating complex overlying layers. However, cavitation thresholds are widely varying in tissues and cavitation requires high intensities to initiate. Either microbubbles[65-67] or nanoparticle have been studied as a method of delivering nuclei into the target region[52]. The addition of intravenously injected microbubbles can enhance the effects of ultrasound and lower the energy requirement for producing heating effect through decreasing the cavitation threshold.[57, 62, 68, 69] In addition, microbubbles and thrombolytic drug can be combined together with HIFU therapy for targeted drug delivery, drug transport acceleration[70-77] and eventually enhancing HIFU. However, the use of microbubbles and nanoparticle, however, requires the systematic injection of foreign particles into the blood stream, and would have a lot concerns regarding the toxicity, efficiency, etc[78].

1.2 The goal of this research

In this study, we will first demonstrate that the integrated PAI and HIFU system can be used to provide excellent guidance for HIFU treatment in both ex vivo and in vivo experiments. Secondly, the integrated system will be modified to monitor HIFU treatment in real time. Finally, we will develop and evaluate a new system based on the integrated system for laser-enhanced particle-free HIFU heating. During the experiment, the laser light will be employed to treat the target area concurrently with HIFU treatment to help induce cavitation, which is the key factor for both HIFU heating and thrombolysis treatment. The finding, for the first time, will potentially allow us to enhance HIFU therapy at a relatively low HIFU intensity level without introducing foreign particles in to the targeted tissue region.

Chapter 2 The integration of photoacoustic imaging and high intensity focused ultrasound

2.1 Introduction

High intensity focused ultrasound (HIFU) has been used as an effective non-invasive method to treat solid tumors deep in the body. During a HIFU treatment, the high intensity ultrasound is delivered to the focal region of the HIFU transducer, and subsequently absorbed by the soft tissue in the focal region. The absorption of HIFU energy induces a rapid temperature rise, which results in tissue coagulation, and finally leads to the irreversible tumor cell death and severe damage to tumor blood vessels in the treated region. [8, 79] The soft tissue outside the focal region will be undamaged because the ultrasound intensity is relative low in those regions.

To improve the effectiveness of HIFU treatment, we need to locate and monitor the treated tissue so that the guidance and feedback on the treatment can be provided.[80] Current imaging modalities such as magnetic resonance imaging (MRI) and ultrasound imaging have been used to visualize the treatment process and monitor the immediate thermal effects.[9, 22, 32, 81, 82] However, MRI makes the treatment cumbersome and expensive. Although ultrasound imaging is inexpensive and can potentially perform with the same HIFU transducer in real time, it has relatively low imaging contrast, sensitivity, and specificity for noninvasive detection.

Photoacoustic imaging (PAI), also called optoacoustic imaging or thermal acoustic imaging, has been developed as a novel promising imaging technique for early

cancer detection.[37, 39-41, 43, 83] PAI is based on the generation of photoacoustic waves by safely depositing short-pulsed optical energy into tissue. Each laser pulse causes a rapid temperature rise on the order of 10 millidegrees. The ultrasonic waves generated due to thermoelastic expansion can be detected with either a single-element ultrasonic transducer or an array of ultrasonic transducers and then used to reconstruct an image.[83] PAI technology is designed to overcome the poor spatial resolution of purely optical imaging yet to retain the high optical contrast in the deep region beyond the depth limit, which is ~ 1 mm, for high-resolution optical imaging, and demonstrated the capability of providing images with optical contrast and ultrasound resolution in regions up to 5 cm deep in soft tissue.[45]

PAI has demonstrated to be capable of monitoring thermal lesions generated by HIFU or other means.[49, 50] A study for PAI guidance of HIFU has also been proposed with the application of time-reversal technique.[84] Currently, PAI and HIFU are performed by two separate systems. When PAI and HIFU are performed separately by two systems, a tissue imaging window for PAI, which utilize both light and ultrasound, and a therapeutic window for HIFU to deliver ultrasound energy will be required. In clinic practice, two tissue windows are sometimes difficult to be identified. In addition, when two separate systems are used, the location of the two systems needs to be known precisely so that the treatment will be performed on the lesion, which is identified on the image. To align the treatment area with the imaging area could be a challenge and may result in the ablation of normal tissue.

One way to improve PAI-guided HIFU is to use an integrated system for PAI and HIFU. The combination of PAI and HIFU is technically possible. In PAI technology, both laser and ultrasound energy are involved in the imaging process. The ultrasonic transducer's sole purpose within the modality is to act as a receiver of the acoustic signals. If the ultrasonic transducer is used as a transmitter to deliver high ultrasound energy to soft tissue, the PAI system potentially has therapeutic applications as a HIFU system.

HIFU can treat soft tissues up to 10 cm, whereas the deep reflection-mode PAI, when a 5-MHz ultrasonic transducer is used, can provide penetration depth up to ~3.8 cm without using any contrast agents.[85] With the aid of PAI contrast agents, the deep reflection-mode PAI should be able to image even deeper. Therefore, a reflection-mode PAI-guided HIFU may be used to treat breast tumor, prostate tumor, and tumors in the lymphatic system, etc..

In this paper, we investigated the feasibility of using an integrated PAI and HIFU system to non-invasively detect the location of the target tissue sample and then plan and perform the HIFU ablation on the target tissue sample. The biggest advantage of a combined reflection-mode PAI and HIFU with one transducer lies on the fact that only one tissue imaging/therapy window is required with this technique, and therefore, it will be much friendly to be used in future clinic practice. Furthermore, with the combined system, the treatment can be performed precisely on the area identified through the obtained image, and therefore, the treatment location can be very precise. This advantage may be of more interest when treating small lesions, which may be identified in early cancer detections.

In the combined PAI/HIFU system, we utilize a reflection-mode PAI (also called PAM)[85, 86] with a standard 5-MHz HIFU transducer as our photoacoustic signal detector. The HIFU transducer also delivers high intensity ultrasound energy to soft tissue during tissue ablations. Our results show that the combined PAI/HIFU is capable of performing imaging and therapy.

2.2 Materials and Methods

Figure 2.1 Schematic of the integrated PAI and HIFU system

Figure 2.1 shows the schematic of the integrated PAI and HIFU system. During PAI mode, a tunable OPO laser (Surelite OPO PLUS; Continuum), pumped by a Q-switched Nd:YAG laser (Surelite III; Continuum) is used to generate laser light. The system operates at 680 nm wavelength with a 10 Hz pulse repetition rate for excitation of the tissue. The produced laser light is directed to a conical lens via a group of prisms,

which enable higher optical energy delivery[85] than the optical fibers-based PAI systems.[86] The laser passing through the conical lens forms a ring-shaped illumination. The ring-shaped light is transmitted to an optical condenser and refocused inside the tissue sample. At the tissue surface, the ring has a diameter of ~5 mm, which has the advantage of reducing the generation of surface photoacoustic signals, and allowing for the improvement in the detection of deep photoacoustic signals.[85, 86] The subsequently generated photoacoustic signals are detected by a 5-MHz focused ultrasonic transducer (SU-108-013, Sonic Concepts), which has a focal length of 35 mm and diameter of 33 mm. The transducer delivers the recorded acoustic signal to a pre-amplifier (5072PR, Olympus-NDT). After signal amplification, the detected photoacoustic signals are collected by a PC through a digital oscilloscope (Tektronix DPO 3034). The transducer is mounted in the middle of the condenser lens and driven by a XYZ-linear translation stage for raster scanning on the tissue sample. Two prisms are used to enable the beam-folding for the 2D scan. Prism Y can only move on the Y direction, whereas prism XY can move on both X and Y direction. This design for PAI has been presented by Song et al.[85] for deep PAI, and proved to generate good-resolution photoacoustic images in deep regions inside soft tissue.

During HIFU mode, the 5-MHz focused ultrasonic transducer was used as a transmitter. At each scanning position, a continuous ultrasonic wave, which was generated by a function generator (HP33250A; Agilent Technologies) and amplified by a 50 dB RF amplifier (350L; ENI Technology, Inc), was sent to the transducer. The transducer, which was driven by PC-controlled motors, induced the HIFU field step by step in the tissue sample.

In order to quantify the actual resolution of our PAI system with the HIFU transducer as a receiver, a well-controlled sample (human hair, $\sim 50\ \mu\text{m}$ in diameter) in water was imaged. Figure 2.2 shows the cross-section of the human hair on a B-mode scan image. We can achieve a lateral resolution of $\sim 270\ \mu\text{m}$ and an axial resolution of $\sim 200\ \mu\text{m}$.

Figure 2.2 The cross-section of a human hair in water.

To test the ability of the system in the detection of optical contrast change before and after HIFU, we performed *in vitro* test in a chicken liver. A slice (2 mm thick) of

chicken liver was imaged first, and then HIFU was used to sonicated a portion of the liver. After HIFU sonication, PAI was used to image the liver slice again.

To further simulate the tumor detections by PAI and localized ablation by HIFU, we embedded a thin slice of swine liver tissue (2-mm thick) between two fresh chicken breast tissues slabs. The thicknesses of the two chicken breast slabs were different. The upper slab was ~1-mm thick, while the lower slab was approximately 10-mm thick and much larger than the upper slab in order to reduce the interference from signals generated at the bottom of the sample. The samples were immersed in water, and air bubbles were carefully removed before PAI. Since the optical absorption in the swine liver tissue is much higher than that in the chicken breast tissue, good image contrast should be achieved between them. During the experiments, PAI was first used to detect the location of the swine liver, and then, HIFU ablation was performed based on the exact position of the swine liver sample identified on the photoacoustic image. After HIFU ablation, PAI was performed again to detect the change on the generated photoacoustic signals.

For the photoacoustic image formation, we take maximum-amplitude-projected (MAP) image. On a MAP image, the maximum value of the photoacoustic signal detected at each scan position is plotted.

2.3 Results

Figure 2.3 (a) shows the photoacoustic image of the chicken liver after a portion of the liver went through the HIFU ablation, whereas figure 3 (b) shows the photograph of the chicken liver. Compared with other untreated region, the HIFU treated region

shows a great enhancement in the amplitude of photoacoustic signals. On the image, the averaged contrast ratio between the treated and untreated region is about 3.6, with a standard deviation of 1.8. The increase in the amplitude of photoacoustic signals after HIFU treatment is consistent with previous results[49, 50]. The increase in the amplitude of photoacoustic signals after HIFU can be caused by a combination of several factors. Notably, the Grüneisen parameter is affected by tissue coagulation.[87] The intensity at the focal region was estimated to be 10^4 W/cm^2 during the HIFU ablation, and the treatment duration was 1 s.

Photoacoustic images of the swine liver tissue in chicken breast tissues before and after HIFU are presented in Figure 2.4. Figure 2.4(a) was taken before HIFU ablation on the swine liver sample and it shows the location of liver tissue and shape, which acted as the guidance for the subsequent HIFU ablation. For HIFU ablation, we chose the scanning area of $5.4 \text{ mm} \times 7 \text{ mm}$ which accurately cover the entire area of the liver and avoid burning the surrounding tissue. The step size of the scanning on the sample was 0.2 mm. At each scanning position, the ultrasonic wave was focused into the sample for 4 s, with a focal intensity of 10^3 W/cm^2 . Compared with Figure 2.4(a), Figure 2.4(b), which is the photoacoustic image after HIFU ablation, reveals the swine liver tissue with approximately the same size and slight increase at PAI contrast, which is shown by the increased photoacoustic signal amplitudes in the MAP image. Figure 2.4(c) and (d) shows the photograph of the liver tissue before and after HIFU ablation.

To quantify the change in the photoacoustic image after HIFU, we calculated averaged enhancement in the amplitude of photoacoustic signals before and after HIFU in

the HIFU treated region. The average enhancement is $\sim 6\%$ with a standard deviation of 4% . The enhancement in photoacoustic signals is small because the ultrasound intensity at the focal region was only 10^3 W/cm^2 , and the treatment duration was 4 s for current HIFU ablation. We anticipate that a higher enhancement in photoacoustic signal should be achieved if a higher ultrasound intensity level at the focal region is used during HIFU ablation, as shown in Figure 2.3.

Figure 2.3 (a) Photoacoustic image of a chicken liver after HIFU ablation. The ultrasound intensity at the focal zone is 10^4 W/cm^2 , the ablation duration is 1 s at each scanning position. (b) Photograph of the chicken liver after HIFU ablation. The HIFU targeted area is outlined on (a).

The results in Figure 2.4 demonstrate that the combined PAI/HIFU system with one transducer is capable of perform PAI-guided HIFU ablation. PAI can be performed to identify the location of the targeted region, and HIFU can then be performed to ablate the targeted tissue. At the end, PAI can be performed again to confirm the HIFU ablation.

Figure 2.4 Photoacoustic images of a piece of swine liver embedded in the chicken breast (a) before the HIFU ablation and (b) after HIFU ablation. The ultrasound intensity at the focal zone is 10^3 W/cm², and the ablation duration is 4 s. (c) and (d) are photographs of the swine liver before and after HIFU ablation, respectively.

2.4 Discussion and Conclusions

An integrated PAI and HIFU system was presented in current research. We demonstrate that with one system, PAI can be used as a guidance and evaluation tool for HIFU ablation. A combined reflection-mode PAI and HIFU with one transducer will only need one tissue window for both imaging and therapy, and therefore, it will be much friendly to be used in future clinic practice. With the combined system, precise alignments between treated areas and planned treatment areas, which is indentified on the image, during the therapeutic phase can be assured relatively easy, and therefore, the ablation can be performed precisely on the area identified through the obtained image.

We have used a 5-MHz HIFU transducer for PAI in this system. Usually, a focused, broadband ($>70\%$ bandwidth) transducer is preferred for the reflection-mode PAI (or PAM). A broadband transducer will provide good axial resolution, whereas the lateral resolution is determined by the focusing effect of the transducer. The drawback of using a broadband transducer is that a broadband transducer usually has a relative low sensitivity. For HIFU application, we usually use narrowband transducer to achieve best energy delivery. When a narrowband transducer is used for PAI, the axial resolution will become worse than that of using a broadband transducer, whereas lateral resolution should be the same because it depends on the focusing effect. However, one advantage of using a narrowband transducer is that a narrowband transducer usually has higher sensitivity than a broadband transducer. In summary, when we use a HIFU transducer for PAI, we will sacrifice the axial resolution, but gain high sensitivity. For deep reflection-mode PAI, a high sensitivity may be of more interest. When we use our HIFU transducer,

which has a fractional bandwidth of $\sim 50\%$, as a PAI receiver, a reasonable axial resolution is obtained (Figure 2.2). Therefore, we believe the proposed technique is feasible and promising.

Additionally, the current system used a single-element transducer for PAI and HIFU, therefore, mechanical scans are required to conduct the imaging process and HIFU ablation. A phased array can be used in the future to reduce the time required for imaging and therapy. We envision that PAI technique may potentially be combined with HIFU ablation for image-guided therapy.

Chapter 3 In-vivo imaging and treatment of solid tumor using integrated photoacoustic imaging and high intensity focused ultrasound system

3.1 Introduction

High-intensity focused ultrasound (HIFU) has been used in clinics as a non-invasive technique for the treatment of solid tumors.[8] During HIFU treatment, a HIFU transducer is used to ablate soft tissue in the focal zone of the HIFU transducer through thermal and mechanical effects produced by HIFU beams. By mechanically scanning the transducer, the whole tumor area can be ablated with little or no damage on the surrounding tissue. The main advantage of this technology is its non-invasive nature, and therefore, HIFU has been used in clinical treatment of several types of cancers such as breast cancer and prostate cancer.[1, 11, 79, 88-90]

To accurately treat a solid tumor, imaging techniques for locating the solid tumor and monitoring HIFU treatment are always performed before and after HIFU ablation. Photoacoustic imaging (PAI) technique is a novel promising imaging modality, which can be used to guide HIFU ablation. PAI is a hybrid technique that can image the distribution of optical absorption deep inside the tissue based on photoacoustic effect. When short-pulsed laser beams irradiate on biological tissues, ultrasonic waves are generated due to pressure rise from transient thermoelastic expansions. The ultrasonic waves, referred as photoacoustic waves, are detected by an ultrasonic transducer and then converted to electrical signal that can be collected by a PC to analyze or form

photoacoustic images. Although several groups showed that magnetic resonance imaging (MRI),[32, 91, 92] thermoacoustic tomography (TAT),[93] ultrasound imaging[25, 94] have the capabilities of monitoring the thermal lesion generated by HIFU in the targeted region, PAI has certain advantages and has already been used to visualize HIFU treatment.[49, 50] One of the advantages of PAI over other imaging modalities is its potential for versatile and minimally invasive molecular imaging for visualization of solid tumors with the assistance of contrast agents such as nanoparticles. Recently, photoacoustic microscopy (PAM) had been used to non-invasively image extravasation and accumulation of gold nanorods within a CT26 murine colon carcinoma tumor *in vivo*. [95] Gold nanorods have also been used to provide high contrast between targeted and nontargeted tissue for photoacoustic molecular imaging *in vitro* and *in vivo*. [96, 97]

We have developed an integrated PAI/HIFU system[98] previously. In this study, we will show the feasibility of the combination of photoacoustic imaging and HIFU treatment with the integrated PAI and HIFU system *in vivo*. PAI will be enhanced by gold nanorods through extravasation *in vivo*. HIFU ablation of the tumor will then be performed under the guidance of PAI.

3.2 Materials and methods

3.2.1 Integrated PAI/HIFU system

Figure 3.1 shows the schematic of the integrated PAI and HIFU system.[98] When the system was operating in PAI mode, pulsed laser light with a 10-Hz repetition rate was produced by a tunable OPO laser (Surelite OPO PLUS; Continuum, Santa Clara, CA) that was pumped by a Q-switched Nd:YAG laser (Surelite III; Continuum, Santa

Clara, CA). The pulse width of the laser was 6 ns and the tunable wavelength range for the OPO laser was from 680 to 980 nm. The generated laser pulses were directed by a couple of prisms and then formed a ring-shaped illumination by a conical lens. A condenser lens was used to make the laser light confocal with a 5-MHz focused ultrasonic transducer (SU-108-013; Sonic Concepts, Bothell, WA) which was mounted in the middle of the condenser lens. The conical and condenser lenses were driven by a 3D translation stage to enable the transducer to mechanically scan the targeted region. Two prisms were used to enable the optical beam-folding for a 2D mechanical scanning. Prism Y could only move on the Y direction, whereas prism XY could move on both X and Y direction. This design has been presented by Song *et al.* [46] for deep PAI, and proved to generate good-resolution photoacoustic images in deep regions inside soft tissue. The ultrasonic transducer scanned above the sample continuously with a speed of 0.5 mm/s and collected data every 0.05 mm along x-axis, while the step size along y-axis was 0.1 mm. It took ~45 min to scan a 10 mm \times 10 mm area. On the tissue surface, the laser spot had a diameter of ~5mm and the laser intensity was restricted to 20 mJ/cm², which complied with the laser safety limit of American National Standards Institute (ANSI). The 5-MHz transducer had a fractional bandwidth of 60% with 35 mm focal length and 33 mm aperture size, respectively. Although the fractional bandwidth is relatively low, it is a necessary tradeoff in an inexpensive integrated imaging and therapy transducer. The transducer was immersed in a water tank which had a window on the bottom sealed with polyethylene membrane. The sample coated with ultrasound gel was laid on the other side of the membrane. The recorded photoacoustic signals by the transducer were amplified through a pre- amplifier (5072PR; Olympus-NDT, Waltham,

MA) and then collected by a PC through an A/D Scope Card (CS21G8-256MS; Gage, Lockport, IL) with a 500-MHz sampling rate.

Figure 3.1 Schematic of the integrated PAI and HIFU system.

When the system was operating in HIFU mode, continuous waves were generated by a function generator (HP33250A; Agilent Technologies, Santa Clara, CA) and amplified by a 50-dB radio frequency amplifier (350L; ENI Technology, Inc., Rochester, NY) before the waves were sent to the ultrasonic transducer. HIFU lesions were induced

at each scanning position before the transducer was stepped 0.2 mm. The actual ultrasound intensity at each position was approximately 3000 W/cm^2 .

3.2.2 In vitro test for imaging resolution and depth

Figure 3.2 (a) B-scan image of a human hair in water. (b) Signal profile at the vertical dashed line position in (a). (c) Signal profile at the horizontal dashed line position in (a).

As the first step, the imaging capability of the system was tested. A sample (human hair, $\sim 50 \mu\text{m}$ in diameter) in water was imaged to quantify the lateral and axial resolutions of the integrated PAI/HIFU system. The hair was placed in the focal region of the focused ultrasound transducer, i.e., 35 mm away from the transducer. The laser wavelength used was 680 nm. Figure 3.2(a) shows the cross-section image of the hair, whereas Figure 3.2(b) and (c) show the corresponding photoacoustic signals at the locations that are marked on the image. From Figure 3.2 (b), the lateral resolution is

estimated to be $\sim 270\text{ }\mu\text{m}$, and from Figure 3.2 (c), the axial resolution is estimated to be $\sim 220\text{ }\mu\text{m}$. Note that the resolutions are all estimated in the focal region of the focused ultrasound transducer. As it moves away from the focal region, the lateral resolution will deteriorate, as shown by Song *et al.* [46]

Figure 3.3 Photoacoustic image of a carbon rod in chicken breast tissue. The surface of the breast tissue is located at 3-mm on z-axis.

To test the imaging depth in soft tissue, we used the integrated PAI/HIFU system to image a buried 500- μm diameter carbon rod in chicken breast tissue. This image was obtained by simply scanning the ultrasonic transducer across the sample, and no signal

averaging was used. The laser wavelength of 800 nm was used for this test to achieve deep penetration. Figure 3.3 shows the carbon rod is clear imaged at a depth of ~40 mm with a signal-to-noise ratio (SNR) of 26 dB.

3.2.3 In vitro test for gold nanorods

Figure 3.4 Normalized PA signals from saline solution and gold nanorod solution as a function of wavelength. Line with circles: pure 0.9% saline solution; line with dots: gold nanorod solution. Error bar represents plus and minus one standard deviation.

During PAI, near-infrared (NIR) light is frequently used to achieve deep imaging depth. However, in comparison to using visible light, the contrast of PAI is low when NIR light is used. Gold nanoparticles can be used to improve the image contrast of PAI. In this study, we used gold nanorods to enhance the PAI detection of tumor in an *in vivo*

small animal model. Prior to animal experiments, the peak optical absorption wavelength of gold nanorods (30-PM-700-1, Nanopartz, Loveland, CO) was measured using integrated PAI/HIFU system. Nanorods suspended in 0.9% saline solution with a concentration of 3×10^{11} nanorods/ml were injected into a clear Polyvinyl chloride (PVC) tube (~1 mm inner diameter). The generated PA signals from nanorods at different laser wavelengths were collected and averaged 64 times. The PA signals from pure saline solution were also collected for comparison with the signals from the nanorods. The same laser power was used for all excitation wavelengths, and the wavelength used was 680 nm. Signals from a photodiode were used to compensate for pulse-to-pulse fluctuations in laser energy. Figure 3.4 shows that strong PA signals are generated from the nanorod solution, whereas the PA signals from pure saline solution-filled tube are very weak. Figure 3.4 also shows that these nanorods produce strongest PA signals at the wavelength of ~685 nm.

3.2.4 Animal preparation and experiment procedure

CT26.WT murine colon carcinoma cells (ATCC, Manassas, VA) were administered subcutaneously on the hip of BALB/c mice weighting about 20 g. 7 to 10 days after the inoculation, tumors were ready to be imaged and treated. Before the experiment, a mouse was anesthetized with a mixture of Ketamine (87 mg/kg body weight) and Xylazine (13 mg/kg body weight). Then hairs at the tumor region were shaved. After shaving, the animal was coated with ultrasonic gel at the tumor area, and placed under the membrane of the water tank for imaging and treatment. During the *in vivo* experiment, the animal was kept under anesthesia by the inhalation of isoflurane gas with a dose of 1% in pure oxygen at a 1-L/min flow rate. A pulse oximeter (PulseSense

VET; Nonin Medical Inc., Plymouth, MN) was used to monitor the heart beat rate and saturation of peripheral oxygen (SpO₂) of the animal. PAI was first performed to get a reference image. Then, gold nanorods with a dose of 9×10^9 nanorods/ g body weight were injected intravenously through tail vein. PAI was performed again 30 minutes after the injection of the nanorods. After PA images were obtained, HIFU treatment on the specific tumor area determined by PA images was performed. HIFU treatment duration was 1 s at each scanning position, and the actual ultrasound intensity at each position was approximately 3000 W/cm². After HIFU ablation, PAI was performed again. Then the animals were returned to their cages, and the recovery process was monitored for the following two weeks in order to evaluate whether the tumor was completely ablated by HIFU. The photographs of HIFU treated area were taken every day.

3.3 Results and Discussion

Maximum-amplitude-projected (MAP) images obtained from the animal experiment are shown in Figure 3.5. Figure 3.5(a) and (b) are PA images before and after injection of nanorods, respectively. Because of the low optical absorption in NIR region, we can only obtain the signals from blood vessels and background tissue with a relatively low optical absorption contrast in Figure 3.5(a) without nanorod injection. The significant change from Figure 3.5(a) to Figure 3.5(b) was caused by the accumulation of nanorods in the tumor, and it revealed the shape and position of the tumor. In addition, the amplitude of photoacoustic signals from the blood vessel increases, because nanorods exist in the circulation system of the mouse. Based on the tumor information shown in the previous images, we planned the HIFU treatment on the tumor area. Figure 3.5(c)

presents the MAP image after the HIFU ablation, the tumor region also shows great photoacoustic signal enhancement comparing with Figure 3.5(a). This enhancement might be also caused by the increase of Grüneisen parameter due to tissue coagulation.[99] Some features in Figure 3.5 (a) and (b) are not shown in Figure 3.5(c) because of the possible position shift during HIFU ablations.

Figure 3.5 Noninvasive MAP images taken before gold nanorod injection (a), after nanorod injection (b), and after HIFU ablation (c). All PA images are normalized by the maximum intensity of all three images, and are shown at the same intensity grayscale.

The HIFU lesion was monitored for about 2 weeks after the HIFU treatment. Figure 3.6(a), 6(b), 6(c) and 6(d) are the photographs taken prior to, right after, 5 days and 16 days after HIFU treatment, respectively. These photographs show the recovery process of the tumor during the two weeks after HIFU ablations, and no tumor growth was observed. The results demonstrate that the tumor was completely ablated by the HIFU treatment.

Figure 3.6 Photographs taken prior to (a), right after (b), 5 days after (c) and 16 days (d) after HIFU treatment. All photos are at the same length scale.

The animal experiment in this study was performed to image and treat subcutaneous tumors. However, the capacity of imaging deep target in the soft tissue was also demonstrated in Figure 3.3. Therefore, this technique will be able to apply for the treatment of relatively deep tumors, such as breast tumor and prostate tumor. In this study, the sole purpose of nanoparticle is to improve imaging contrast. The application of nanoparticle-based contrast agents can greatly extend the current technique. From imaging point of view, nanoparticle-based contrast agents help PAI to image deeper within tissue with enhanced contrast because nanoparticles are usually designed with peak absorption in the NIR region. In addition, targeting peptides and antibodies can be conjugated to the nanoparticle surface for cell specific contrast and molecular imaging, which may be used to target specific tumor cells during PAI-guided HIFU. The application of gold nanoparticles can also potentially enhance HIFU by enhancing cavitation effect.[100]

3.4 Conclusion

In summary, we demonstrated from one case that photoacoustic imaging could act as the guidance and evaluation tool for HIFU treatment in *in vivo* tests. The application of gold nanorods greatly increased the imaging contrast of PAI, and as a results, the solid tumor was identified and ablated by HIFU. The future work may include of using actively targeted nanoparticles for photoacoustic molecular imaging and guiding the subsequent HIFU treatment.

Chapter 4 Real-time monitoring of high-intensity focused ultrasound ablations with photoacoustic technique: an in vitro study

4.1 Introduction

High intensity focused ultrasound (HIFU) is rapidly growing as an accepted clinical therapeutic modality enabling non-invasive tissue ablation[2]. During HIFU treatment, focused ultrasound energy is delivered into soft tissue and high acoustic intensity is achieved in the focal zone of the ultrasound transducer, whereas acoustic intensity is low in regions outside the focal zone. After the high intensity ultrasound is absorbed by the soft tissue, local heating is created, and subsequent cell death is induced by coagulation necrosis[8, 9, 18, 25, 79, 101-104]. HIFU is a non-invasive therapy modality that avoids the insertion of probes into the targeted tissue. The high power focused ultrasonic beams employed are generated from sources placed either outside the body (for treatment of tumors of the liver, kidney, breast, uterus, pancreas and bone[8]) or in the rectum (for treatment of the prostate[18, 19, 21, 102, 103, 105-107]). Currently, thousands of patients are treated with HIFU every year worldwide. The role of HIFU in oncology is likely to continue expanding as devices become more widely available.

HIFU requires a suitable imaging technique to visualize the target and monitor the tumor ablation process[2, 79, 108]. While imaging guidance could provide the encouragement for increased clinical use and expand applications of HIFU, the choice of imaging platform to employ is still a matter of debate. Currently, the majority of clinical HIFU treatments is performed with ultrasound guidance. Although ultrasound imaging is inexpensive and can be performed in real time[23-25, 109], it has relatively low imaging

contrast, sensitivity, and specificity for noninvasive detection. In addition, temperature rise during HIFU cannot yet be accurately measured with ultrasound, especially when cavitation occurs, although efforts have been made[26-30]. In some respects, magnetic resonance imaging (MRI) is a more viable imaging technique to guide HIFU therapy because it can produce temperature images[8, 22, 80-82]. However, MRI makes the treatment expensive. In addition to the high equipment and operating costs, MRI requires the patient to be placed inside a magnet. The magnet bore restricts patient access for HIFU treatment and complicates positioning of the HIFU applicator. In some MRI modes (such as head and neck imaging), special RF coils are used to fit closely to the patient's anatomy, and these coils will interfere with HIFU transducer placement.

Photoacoustic imaging (PAI), also called optoacoustic imaging or thermoacoustic imaging, has been developed as a novel promising imaging technique for early cancer detection[37-41, 44]. PAI is based on the generation of photoacoustic waves by safely depositing short-pulsed optical energy into tissue, and then detecting these waves with a diagnostic imaging transducer, acting as a receiver to uncover local tissue abnormalities[42-44]. PAI overcomes the limitations of other existing modalities and combines optical contrast with ultrasonic resolution. PAI has demonstrated imaging depth up to 5 cm[45] with the imaging resolution (from 2 μm to 500 μm) scalable to the imaging depth[42, 110]. Because PAI is based on optical absorption, it can be implemented quickly and inexpensively, with relatively simple instrumentation requirements and no ionization.

PAI has demonstrated the capability to monitor thermal lesions generated by HIFU or other means[47-50, 87, 111]. However, all study up to date was focused on the monitoring of temperature with PAI during HIFU. Although PA signals are sensitive to temperature rise, monitoring temperature with PAI during HIFU may not provide accurate indication for tissue coagulation. The generation of PA signals depends on the optical properties of the sample. PA signals will change if the optical properties of the sample changes. For example, tissue samples may coagulate at a constant temperature, e.g. 50 °C, and therefore, the optical properties of tissue sample will change under the constant temperature. As a result, PA signals will change at this constant temperature. In other words, PA signals are related to heating rate, and the signal amplitude is a function of temperature and heating duration, which are coupled parameters during the coagulation process and cannot be separated. Therefore, the utilization of PAI to monitoring temperature rise during thermal ablation without considering heating duration may not be possible.

In this paper, we propose to use PAI to monitor thermal dose, which is a function of heating duration and temperature, and a direct indicator for tissue coagulation, during HIFU exposure. We employed an integrated PAI and HIFU system we developed previously[112] to monitor HIFU ablation on beef kidney in real time. Two ultrasonic focused transducers were employed to deliver HIFU energy and receive photoacoustic signals. Temperature rise during HIFU ablation was also measured with a thermocouple and the thermal dose was calculated. Therefore, PA signals were related to tissue coagulation through thermal dose. We demonstrated that a relationship between PA

signal amplitude and thermal dose should be developed and used to monitor thermal ablation.

4.2 Materials and methods

Figure 4.1 Diagram of experimental setup.

The experimental setup is shown in Figure 4.1. A tunable Optical parametric oscillator (OPO) laser (Surelite OPO PLUS; Continuum, Santa Clara, CA), pumped by a Q-switched Nd:YAG laser (Surelite; Continuum, Santa Clara, CA) with a pulse repetition rate of 10 Hz, was employed as the irradiation source. The generated laser pulses were directed by three prisms and then formed a ring-shaped illumination by a conical lens. A condenser lens was used to make the laser light confocal with a 5-MHz HIFU transducer (SU-108-013; Sonic Concepts, Bothell, WA) which was mounted in the middle of the condenser lens. A 10-MHz focused ultrasonic transducer (37.5 mm focal length; 65.81%

-6-dB fractional bandwidth, Olympus NDT, Waltham, MA)) which acted as a photoacoustic detector was aligned to be confocal with the HIFU transducer and laser light prior to the measurements. Both transducers were immersed in a water tank which had a window on the bottom sealed with a piece of polyethylene membrane. Tissue sample coated with ultrasound gel was laid on the other side of the membrane. A 25- μ m diameter, T type thermocouple was placed 0.5 mm away from the focal point of transducers on the sample surface to measure the temperature rise during the HIFU ablation as well.

During the experiment, a function generator (HP33250A; Agilent Technologies, Santa Clara, CA) was used to provide the source signals to drive the HIFU transducer. The source signals were amplified by a 50-dB radio frequency amplifier (350L; ENI Technology, Inc., Rochester, NY) and were then sent to the HIFU transducer. The recorded photoacoustic signals from the focal region of the HIFU transducer by the 10-MHz transducer were amplified through a pre-amplifier (5072PR; Olympus-NDT, Waltham, MA) and then collected by a PC through an A/D Scope Card (CS21G8-256MS; Gage, Lockport, IL) with a 125-MHz sampling rate.

Imaging data acquisition and the generation of HIFU waves from the function generator were synchronized, and triggered by the laser system. To avoid signal interference between HIFU and PAI, HIFU signals were turned off for 10 ms after each 190 ms sonication. The 10 ms time window allowed one clear PA signal to be collected from the HIFU treated spot while the heating process was not disrupted. The temperature

induced by HIFU was monitored at the same time with the T-type thermocouple. Figure 4.2 shows the time sequence of imaging data acquisition and HIFU treatment.

Figure 4.2 Time sequence of data acquisition and HIFU waves.

Thermal dose was calculated using the formula suggested by Sapareto and Dewey [113]. Thermal dose at 43°C is given by the relationship:

$$TD_{43} = \sum_{t=0}^{t=final} R^{43-T} \Delta t \quad (1)$$

where TD_{43} is the equivalent time at 43°C, R is 0.5 when T is above 43°C and 0.25 when T is below 43°C, T is the temperature during Δt . A thermal dose of 240 equivalent minutes at 43 °C is widely regarded as the critical value for tissue coagulation.

4.3 Results and Discussion

Figure 4.3 Results from five separated experiments with an intensity of $1000\text{W}/\text{cm}^2$, 14s duration. (a), (b) the averaged PA amplitude and temperature with standard error of the mean (SEM), respectively, (c) the relation between the PA amplitude and the calculated thermal dose from the averaged temperature, and (d) photographs of beef kidney after HIFU treatment.

Figure 4.3 shows the averaged results of five experiments with an HIFU focal intensity of $1000\text{ W}/\text{cm}^2$ and 14-second duration in different beef kidney samples. In Figure 4.3(a) and (b), the averaged PA amplitude and measured temperature with standard error of the mean (SEM) are presented, where SEM shows the range for the averaged PA amplitude. In the beginning part of the HIFU ablation, both the PA

amplitude and temperature keep increasing. After about 8 s, the PA amplitude and temperature tends to reach a constant value because the targeted area of the sample is fully coagulated. Figure 4.3(c) shows the PA amplitude as a function of calculated thermal dose from measured temperatures by the T-type thermocouple. It shows that the relative constant amplitude occurs at TD_{43} of around 240 minutes at 43 °C, which indicates the coagulation of tissue. Additionally, in comparison with the beginning of the ablation, PA signal amplitude increased 3 times at the end of HIFU ablation. This result implies that PA detection is highly sensitive to detect HIFU ablation. Figure 4.3(d) shows the photograph of the lesion generated under this exposure which was on the surface of the renal cortex tissue of beef kidney.

As we have mentioned previously, HIFU ablation process is a dynamic process, and the tissue property change, which results in the change in PA amplitude, is a function of both temperature and heating duration. An experiment such as the one shown in Figure 4.3 shows the combined effect of both temperature and heating duration. To separate the effect of these two factors on PA signals, we conducted the follow experiments.

To monitor the sole effect of temperature, we used HIFU to ablate the targeted sample for 40 s at 1000 W/cm² focal intensity to make sure the targeted tissue is fully coagulated, i.e., no more tissue property change even if the high temperature is maintained. Then HIFU was turned off, and both PA signals and temperatures were recorded during the cooling stage. Because the tissue sample was already completely

coagulated, the changes in PA signals were purely induced by the changes of temperature during this process. Figure 4.4 shows the recorded PA amplitude as the function of temperature. We can observe a linear relation between PA amplitude and temperature. This linear relationship is not unexpected because it has been shown by others *in vitro* [114].

Figure 4.4 PA amplitude as the function of temperature and the linear fit. The coefficient of determination $R^2=0.8727$.

To monitor the sole effect of heating duration, we placed a piece of beef kidney (3 mm thick) into a constant 50°C water bath. PA signals generated from the surface of the beef kidney were monitored continuously. A T-type thermocouple was also placed at the tissue surface to monitor the temperature. Throughout the experiment, the temperature at the tissue surface stayed at 50 °C \pm 0.2 °C. The recorded PA amplitude is presented in Figure 4.5. From Figure 4.5(a), we observe that PA amplitude increases initially and then

after about 3 minutes, PA signals stays at a constant level. Figure 4.5 (b) shows the calculated thermal dose, which shows that PA amplitude stays relative constant beginning around 240 TD₄₃ minutes, which indicates the tissue is fully coagulated.

Figure 4.5 (a) PA amplitudes from a beef kidney sample placed in a 50°C temperature water bath; (b) the relation between the PA amplitude and the calculated thermal dose.

Figure 4.5 indicates that PA amplitude changes under a constant temperature over an appreciate time. This result is not unexpected because tissue coagulation occurs at a constant temperature, e.g. 50 °C, and tissue optical properties change during the coagulation. As a result, PA signals will change. Therefore, it may not be proper to monitor the temperature changes during HIFU ablation by using PA signal amplitude because HIFU ablation may not induce instantaneous change in temperature. If HIFU treatment could induce nearly-instantaneously temperature rise, then PA detection would be accurate correlated to temperature at the beginning stage of the treatment.

4.4 Conclusion

In summary, there are three findings from this study. The first finding is that PA amplitude tends to have a saturation (relative constant) stage after the soft tissue is completely coagulated, which is indicated by a thermal dose of 240 or more equivalent minutes at 43 °C. Therefore, it is safe to conclude that the saturation of PA amplitude indicates the completed tissue coagulation. The second finding is that PA technique may not be used to detect temperature rise during thermal ablation because PA signal changes under a constant temperature. Combined with our first finding, we believe that it will be more appropriate that a relationship between PA signal amplitude and thermal dose should be developed and used to monitor thermal coagulation. The third finding is that the change in PA amplitude during HIFU is about 3-fold (Figure 4.3). Therefore, the sensitivity of PA detection for HIFU lesion is sufficient high.

Based on the above findings, we believe that monitoring thermal dose may be a more appropriate method in thermal ablation process than monitoring temperature by PAI, since the monitoring of temperature changes through the detected PA signals during thermal ablation may not be feasible. This conclusion is based on the fact that the detected PA signals can change under a constant temperature, and temperature rise may not be instantaneous during HIFU treatment. Based on our current results, the saturation of PA signal should be used as the indicator for tissue coagulation.

Chapter 5 Enhanced-heating effect during photoacoustic imaging-guided high-intensity focused ultrasound

High-intensity focused ultrasound (HIFU) is a truly non-invasive thermal-ablation technique that avoids insertion of probes into targeted tissue. HIFU works through rapidly depositing high-intensity ultrasound energy into a small region to induce cell death, primarily by hyperthermia, after high-intensity ultrasound is absorbed by soft tissue[8, 9, 79, 104]. HIFU has been successfully demonstrated in animal models of cancer and in limited clinical studies in the United States[2].

To perform HIFU treatment non-invasively, an imaging technique is required. Photoacoustic imaging (PAI) is one of the imaging modalities[43, 44] currently being studied to monitor HIFU therapy. PAI is a promising non-ionizing and non-invasive biomedical imaging technique based on the photoacoustic effect [44] with simultaneous sensitive optical contrast and high ultrasonic resolution. This imaging technique has been successfully applied for detecting early cancers[38, 44, 115] and monitoring thermal lesions generated by HIFU or other means[47, 48].

In this study, we report an enhanced-heating effect during PAI-guided HIFU therapy. Further study shows that this enhancement is due to the nucleation of cavitation during the PAI-guided HIFU process. This new finding demonstrates another advantage of PAI-guided HIFU. The technique will be able to facilitate the HIFU treatment process by enhancing heating at a relatively low HIFU intensity, and without the injection of micro- or nano-size particles into the blood stream.

Figure 5.1 System schematic.

Figure 5.1 shows the schematic of the PAI-guided HIFU system. A tunable optical parameter oscillator (OPO) laser (Surelite OPO PLUS, Continuum, CA), pumped by a Q-switched Nd:YAG laser with a pulse repetition rate of 10 Hz, was employed as the irradiation source. The generated laser pulses were directed by a couple of prisms, and then formed into a ring-shaped illumination by a conical lens. A condenser lens was used to make the laser light confocal with a 5-MHz HIFU transducer (SU-108-013, Sonic Concepts, WA) (35 mm focal length), which was mounted in the middle of the condenser lens. A 10-MHz focused ultrasonic transducer (V315, Olympus NDT, MA) (37.5 mm focal length; 70% -6-dB fractional bandwidth), which acted as a photoacoustic signal detector, was aligned to be confocal with the HIFU transducer and laser light prior to the measurements. The 10-MHz PA detector can also be used as a passive cavitation detector

(PCD) to detect cavitation events by sensing the broadband acoustic emissions generated by the collapse of bubbles during HIFU ablation. Both 10-MHz and 5-MHz transducers were immersed in a water tank, which had a window on the bottom. The window was sealed with a polyethylene membrane. Samples coated with ultrasound gels were laid on the other side of the membrane. A 50- μm diameter, T-type thermocouple was inserted into the tissue sample through a needle and placed 0.5 mm away from the focal point of the HIFU transducer to measure the temperature rise during the HIFU ablation. In all experiments, beef kidney samples were used. The laser intensity on the tissue surface was measured to be 18 mJ/cm^2 .

During the experiment, a function generator (HP33250A, Agilent Technologies, CA) was used to provide the source signals to drive the HIFU transducer. The source signals were first amplified by a 50-dB radio frequency amplifier (350L, ENI Technology, Inc., NY), and then sent to the HIFU transducer in order to induce thermal lesions in the sample. During PAI-guided HIFU, burst HIFU waves with 95% duty cycle were transmitted by the HIFU transducer with a repetition rate of 5 Hz in order to avoid signal interference from HIFU on PAI. Therefore, a clear PA signal could be collected by the 10-MHz transducer at 5 Hz when the HIFU waves were off. Because the laser system was running at 10 Hz, 50% of the laser shots illuminated the tissue sample when HIFU was running. During the PAI-guided HIFU model, signals from these 50% of the laser shots were discarded due to the strong interference between the HIFU waves and the PA signals.

Figure 5.2 Temperature enhancement during PAI-guided HIFU. Lines with stars and circles represent the temperature measured by a T-type thermocouple during HIFU exposure when PAI system was on and off, respectively.

During temperature measurement, we found that there was a temperature enhancement when the laser system was operating (PAI was on) during HIFU ablation. Figure 5.2 shows an example of the measured average temperature with standard deviation (STD) from five HIFU sonications through the T-type thermocouple. In these measurements, HIFU focal intensity level was 1000 W/cm^2 , and the sonication duration was 20 seconds. Although no temperature rise could be observed when the PAI system was operating alone, (i.e., HIFU exposure was stopped), there was clearly a temperature enhancement of $\sim 15^\circ\text{C}$ when the PAI system was operating during HIFU exposure. This

result indicates that the HIFU heating is significantly enhanced by the assistance of laser light.

Figure 5.3 Photograph of HIFU lesions inside a tissue sample after HIFU exposure.

After HIFU exposure, the tissue sample was cut open, and a photograph of the lesions was taken. Figure 5.3 shows a photograph of HIFU lesions inside the tissue sample. Each HIFU lesion was induced by a single HIFU sonication. We can clearly observe that the sizes of the HIFU lesions are bigger when the PAI system is on in comparison with that of when the PAI system is off. In addition, from one example, the measured lesion volumes were 3.52 mm^3 (with the laser on) and 1.43 mm^3 (with the laser

off), respectively. This result shows great enhancement in HIFU ablation due to the presence of laser light. The histological results further confirm that HIFU heating is enhanced when PAI and HIFU systems are operating concurrently. Additionally, empty cavities were observed in the central region of the HIFU lesions and suggested that cavitation might have occurred during the heating process when the laser system concurrently illuminated the sample.

To further confirm the occurrence of cavitation and explain the enhanced heating during PAI-guided HIFU, the 10-MHz photoacoustic detector was used as a PCD [51] to detect broadband acoustic emission from the HIFU focal zone. During this test, HIFU was running continuously with different focal intensities and sonication duration of 20 s, and PCD signals were collected with the laser system on and off. The PCD received two types of signals. The first type of signals was sound scattered by the tissue sample, which consisted of primary 5-MHz waves from HIFU. The second type of signals was sound emission from cavitation, which consisted of higher harmonics of the 5-MHz waves. In order to separate the emissions of cavitation from the 5 MHz HIFU waves, a 10-MHz high-pass filter was used. With this system, an abrupt increase in higher harmonics of the 5-MHz waves could appear in the signal spectra when cavitation occurred. For data collection, detected PCD time-domain signals were amplified by a pre-amplifier (5072PR, Olympus-NDT, MA), captured by the GageScope (CS21G8-256MSn Gage, IL), and then downloaded to a personal computer. At each HIFU intensity level, five HIFU lesions were induced on the sample by five HIFU sonications. The number of HIFU lesions with acoustic cavitation at different HIFU intensity levels was counted, and the results are shown in Table 5.1. It is shown that acoustic cavitation occurred at a lower HIFU

intensity (800 W/cm^2) with the laser illumination. However, without the laser illumination, cavitation would not occur until the HIFU intensity reached 1700 W/cm^2 . Cavitation has been demonstrated to enhance HIFU heating by increasing the effective ultrasound absorption[116]. Therefore, the HIFU heating enhancement at a relatively low HIFU intensity when the PAI system was operating in this study was due to the induced acoustic cavitation in soft tissue.

Table 5.1 Number of HIFU lesions with cavitation from five HIFU sonications at each HIFU intensity level with laser on and off.

Laser on		Laser off	
HIFU intensity (W/cm^2)	Number of lesions with cavitation	HIFU intensity (W/cm^2)	Number of lesions with cavitation
600	0	1500	0
700	0	1600	0
800	3	1700	4
900	5	1800	5
1000	5	1900	5

While the application of HIFU therapy is expanding, the concerns related to HIFU treatment include prolonged treatment time for large tumors and skin burns. To reduce the prolonged treatment, it is necessary to enhance the heating induced by HIFU exposure. In general, to enhance HIFU heating, we can simply employ ultrasound waves with higher intensity levels. However, high-power output will induce severe skin burns and also present great challenges for the design of the HIFU system, including the design of

transducers and the electronic circuits. An alternative to very high ultrasound intensity is to increase the local ultrasound absorption so that more ultrasound energy can be deposited in the local region at a relatively low HIFU intensity level. The introduction of cavitation has been investigated as a mechanism to increase the local ultrasound absorption and enhance heating in HIFU [51, 52]. Cavitation has been shown to yield elevated heating rates above those produced by classical absorption in tissue [117, 118] and can provide a means for improving the efficacy of HIFU treatment. However, pre-existing nucleation sites for cavitation are not omnipresent in most tissues in vivo. Either ultrasound contrast agents (UCA) [66, 119, 120] or nanoparticles have been studied as methods of delivering nuclei into the target region[52]. The use of UCA and nanoparticles, however, requires the systematic injection of foreign particles into the blood stream, and would cause much concern regarding the toxicity, efficiency, etc.

This letter reports a particle-free, photo-enhanced HIFU heating method with the utilization of a diagnostic laser system. HIFU heating was enhanced through inducing cavitation in soft tissue by the combination of laser light and ultrasound. In comparison with the other means to enhance HIFU heating, the current technique does not involve the use of any nanoparticles or UCA. The other advantage of the current technique is that a diagnostic laser system for PAI can be used. Therefore, the heating enhancement can be easily achieved while the treatment process is monitored by PAI.

Chapter 6 Laser-enhanced cavitation during high intensity focused ultrasound: an in vivo study

6.1 Introduction

High intensity focused ultrasound (HIFU) is a truly non-invasive thermal-ablation technique. HIFU works through rapidly depositing high intensity ultrasound energy into a small region to induce cell death primarily by hyperthermia after high intensity ultrasound is absorbed by soft tissue[8, 9, 79]. While the application of HIFU therapy is expanding, one concern related to HIFU treatment is the prolonged treatment time for large tumors because HIFU lesion is relatively small for each HIFU shot.

Cavitation has been shown to yield elevated heating rate above those produced by classical acoustic absorption in tissue[51, 117, 118, 121-123] and can provide an effective method to improve the efficiency of HIFU treatment. However, pre-existing nucleation sites for cavitation are not omnipresent in most tissues *in vivo*. Many research efforts have been made to create nucleation sites for cavitation and reduce cavitation threshold. Both ultrasound contrast agents (UCA)[66, 67, 119, 120, 124, 125] and nanoparticles have been studied as methods to deliver cavitation nuclei into the targeted region[52, 100]. The use of UCA or nanoparticle, however, requires the systematic injection of foreign particles into the blood stream, and would have a lot of concerns regarding the toxicity, efficiency, etc.

Laser light has been widely used to induce cavitation through optical breakdown. This procedure is generally performed with high intensity light, and mostly limited to

clear media or sample surfaces[126, 127]. Hence the application of this technique is limited in the *in vivo* applications, where treatments in a certain depth in turbid media are often desired.

In a previous study[128], we reported an enhanced heating effect during photoacoustic imaging-guided HIFU therapy. The results suggested that cavitation was enhanced when a diagnostic laser light beam illuminated the sample concurrently with HIFU radiation. Two features were highlighted in this previous study: 1) a diagnostic laser light beam was used, and the laser fluence was low and under the safety limit recommended by American National Standards Institute[129]; 2) cavitation was observed under the surface layer in a turbid medium. These results motivate us to further study the feasibility of laser-enhanced cavitation during HIFU, and test the limit of this technique.

In the current study, we further investigated laser-enhanced cavitation effect during HIFU in an *in vivo* experiment. Specifically, we investigated the effect of laser on cavitation threshold as a function of laser wavelength, HIFU duration, and treatment depth. The significance of this study lies in the fact that it may develop a technique to facilitate cavitation during HIFU with a diagnostic laser system; hence, HIFU heating can be enhanced without introducing foreign particles into the targeted tissue region.

6.2 Materials and Methods

6.2.1 Experimental system

Figure 6.1 System schematic.

A block diagram of experimental setup is shown in Figure 6.1. A Q-switched, Nd:YAG laser pumped, tunable optical parameter oscillator (OPO) laser (Surelite OPO PLUS, Continuum, Santa Clara, CA) with a pulse repetition rate of 10 Hz (5-ns pulse width), was employed as the irradiation source. The generated laser beam was formed into a ring-shaped illumination on a condenser lens, which was used to mount a 5-MHz HIFU transducer (SU-108-013, Sonic Concepts, Bothell, WA) (35 mm focal length) in the center hole. The condenser lens focused the laser beam underneath the HIFU transducer, and the optical focus overlapped with the ultrasound focus. A 10-MHz focused ultrasonic transducer (V315, Olympus-NDT, Waltham, MA) (37.5 mm focal length; 70% -6-dB fractional bandwidth), which was placed at a 90-degree angle with the

HIFU transducer and acted as a passive cavitation detector (PCD), was aligned to be confocal with the HIFU transducer and the laser beam prior to HIFU treatments. The signal detected by the PCD was directed to a pre-amplifier (5072PR; Olympus-NDT, Waltham, MA). Then, the resulting signals were captured by a data acquisition card (GageScope, CS21G8-256MSn Gage, Lockport, IL), and filtered by a 10-MHz high-pass filter to remove contributions from the HIFU fundamental and second harmonic frequencies in order to ensure that the detected signals were mainly received from broadband acoustic emissions of cavitation. Both the 10-MHz and 5-MHz transducers were immersed in a water tank that has a window on the bottom. The water tank was filled with degassed water, and the window at the bottom was sealed by a piece of polyethylene membrane.

During each experiment, the source signals were generated by a function generator (HP33250A, Agilent Technologies, Santa Clara, CA), and amplified by a 50-dB radio frequency amplifier (350L, ENI Technology, Inc., Rochester, NY), before they were sent to the HIFU transducer through a matching network to induce cavitation in the sample. Laser light was applied to the sample surface concurrently with HIFU sonications.

6.2.2 In vivo experiment

During the *in vivo* experiment, mice (BALB/c, 8-10 weeks old, female or male) were used. All animals have been handled and cared for in accordance with the Guide for the Care and Use of Laboratory Animals, and the procedures were approved by the Institutional Animal Care and Use Committee at the University of Kansas. Before each

experiment, one animal was anesthetized with a mixture of ketamine (87 mg/kg body weight) and xylazine (13 mg/kg body weight) and shaved in the leg region. The shaving procedure included the use of standard surgical hair removal lotion because hairs interfere with ultrasound propagation. After shaving, the animal was maintained under anesthesia with an isoflurane gas anesthesia machine (1-2% isoflurane in pure oxygen) for at least one hour to allow the animal to reach equilibrium body condition. Surgical tape was used to gently secure the animal onto a warmed pad. A custom-designed animal holder was also used to fix the animal with ear-pins and a tooth-pin. The animal was then secured underneath the membrane at the bottom of the water tank for the subsequent experiment. Ultrasound coupling gel was applied to the top surface of the sample to provide coupling between the membrane and the sample surface. Heart-rate and blood oxygenation were monitored with a pulse-oximeter during the experiment, and breathing was visually monitored.

During the experiment, different combinations of laser intensities and ultrasound pressures were applied to the leg muscle of the animal, and the generated cavitation signals were detected by the PCD to determine the pressure thresholds[118] for cavitation. Laser wavelengths in near-infrared region such as 760 and 960 nm were used in order to achieve deep penetration depth.

To obtain HIFU pressure inside the tissue sample, we first calibrated the HIFU transducer with a standard hydrophone, and then a simulation process was employed to calculate the HIFU focal pressure in the tissue sample. During the simulation process, a finite difference time domain (FDTD)[130] was used. The laser fluence was first

measured at the surface of the tissue sample. Then Beer's law was used to estimate the laser fluence inside the tissue by assuming a diffusion process[131].

In order to test the capability of generating cavitation at different depths, we used chicken breast tissues with different thicknesses to cover the region of interest on the small animal. During the experiment, the confocal point of the transducers and the laser was carefully aligned into a leg of the small animal at the desired depths, which were 5 mm and 10 mm from the top sample surface in this study.

6.3 Results

The measured cavitation thresholds are shown in Figure 6.2. Figure 6.2(a) shows the measured cavitation threshold at 5 mm depth when the laser wavelength is 760 nm with a 2-second HIFU sonication. The result shows that the cavitation threshold decreases as the laser fluence increases. When no laser is applied, the detected cavitation threshold is 9.80 MPa. When the surface laser fluence is increased to 50 mJ/cm^2 , which corresponds to a fluence of 10.7 mJ/cm^2 in the HIFU focal region, the measured cavitation threshold is reduced to 7.89 MPa. Figure 6.2(b) shows the results with the similar parameter settings but the HIFU treatment depth is 10 mm. At this depth, the measured cavitation threshold is similar between with and without laser (10.43 MPa versus 10.31 MPa). By using Beer's law, we estimate that the laser fluence at the HIFU focal spot is only 2.3 mJ/cm^2 , which is very low and may explain the reason why laser has little effect on enhancing cavitation.

Figure 6.2 *In vivo* measurements of cavitation pressure threshold. The mean acoustic cavitation thresholds from five measurements were plotted as a function of laser fluence at the sample surface. Error bars are the standard deviations of five measurements. (a) 760 nm laser wavelength, 5 mm treatment depth, 2s HIFU duration time. (b) 760 nm laser wavelength, 10 mm treatment depth, 2s HIFU duration time. (c) 960 nm laser wavelength, 10 mm treatment depth, 2s HIFU duration time. (d) 760 nm laser wavelength, 10 mm treatment depth, 4s HIFU duration time.

Figure 6.2(c) shows the results when laser wavelength 960 nm is used for 10-mm treatment depth. As compared with Figure 6.2(b), it shows that using laser wavelength

960nm reduces the cavitation threshold slightly more than using 760 nm wavelength, although the differences are in the range of error. The major difficulty at this depth is that the laser intensity drops to a very low level, and therefore, the enhancement effect on cavitation threshold becomes low. However, longer wavelength lights should have advantages to enhance cavitation in the deep region because that as the laser wavelength increases in near-infrared (NIR) region, light can propagate further, and therefore retain more energy in a certain treatment depth[132-134].

Figure 6.2(d) shows the measured cavitation thresholds at 10 mm depth with 760 nm laser wavelength and a 4-second HIFU sonication. When laser light is applied, the cavitation threshold is reduced from 9.50 MPa to 8.76 MPa. As compared with Figure 6.2(b), whereas the only difference is the duration of HIFU sonication, Figure 6.2(d) shows that laser-enhanced cavitation can be facilitated by longer HIFU sonication duration.

6.4 Discussion and conclusions

In this study, we showed *in vivo* results for laser-enhanced cavitation effect during HIFU. The results suggest that cavitation effect can be enhanced when laser light is applied to the sample during HIFU sonications. The magnitude of the enhancement, however, seems related to the applied laser fluence. The enhancement will be greater if the applied laser fluence is higher. Laser wavelength and HIFU duration all have effects on the detected cavitation threshold. The major limitation of this technique will be the depth because light is strongly scattered in soft tissue.

Laser light is well-known for its ability to nucleate cavitation through vaporization[127, 135]. To vaporize the surrounding fluid through either optical absorption or optical breakdown, high optical intensity is needed. In this study, however, we showed that with the combination of laser and ultrasound, cavitation was enhanced at a relatively low optical fluence, which complies with the laser safety limit for human recommended by American National Standards Institute[129]. Therefore, the cavitation effect showed in this study is likely due to the combination effect of laser and ultrasound, not laser alone.

In summary, concurrent light illumination during HIFU has the potential to enhance cavitation by reducing cavitation threshold. In comparison with the other methods to enhance HIFU, this technique does not involve the use of any nanoparticles or ultrasound contrast agents.

Chapter 7 Laser enhanced high-intensity focused ultrasound thrombolysis: an in vitro study

7.1 Introduction

Catheter-based ultrasound has been extensively studied as an efficient method to treat deep venous thrombosis (DVT) clinically[53-59]. However, these methods require the catheter to be placed within the blood clot in order to induce mechanical disruption through oscillating wires at high frequency and high intensity. Although catheter-based ultrasound provides an invasive way for thrombolysis, it has shown that the acoustic energy has the ability to dissolve the clots into small debris without causing arterial damage, which is the basis of non-invasive ultrasonic treatment.

High intensity focused ultrasound (HIFU) is one of the non-invasive methods to primarily treat abnormal tissue thermally through hyperthermia[8, 9, 79]. In HIFU ablation, a rapid temperature elevation due to high energy deposition rate results in the tissue damage. However, in pulsed-HIFU exposures with low duty cycle, which is used for thrombolysis, energy deposition rates are low enough that temperature rises are well below the threshold for thermal damage. Thus, the effect of clot disruption are obtained more mechanically and cavitation effect are considered to make the biggest contribution during the process[54, 57, 60-62]. When cavitation occurs, the growth and collapse of bubbles in a sound field at high frequencies produce microstreaming vortices in sufficient magnitude, which can dissolve thrombus[136, 137].

The applications of thrombolysis by HIFU treatment alone are limited and have a relatively low thrombolysis efficiency[63, 64], so either microbubbles or thrombolytic drugs are applied during focused ultrasound exposure to enhance thrombolysis. The addition of intravenously injected microbubbles can enhance the effects of ultrasound and lower the energy requirement for producing ultrasound-mediated thrombolysis through decreasing the cavitation threshold. This enhancement has been shown in several studies[57, 62, 68, 69]. Also, a few of studies[138] have shown that HIFU can improve thrombolysis while applying thrombolytic agent by reducing the dosage of the drug and lowering the risk of hemorrhagic events, but increasing its efficacy. In addition, microbubbles and thrombolytic drug can be combined together for targeted drug delivery, drug transport acceleration[70-77] and eventually enhancing thrombolysis. However, the use of microbubbles and thrombolytic drugs requires the systematic injection of foreign particles into the blood stream, and would have a lot concerns regarding the toxicity, efficiency, etc[78].

In our recent study[139], we found that when the laser system of photoacoustic imaging (PAI) is running simultaneously with HIFU therapy, an enhanced heating effect can be observed due to low cavitation threshold at a relatively low HIFU intensity. This finding potentially allows us to enhance HIFU heating without introducing foreign particles in to the targeted tissue region. Also, we expect that this discovery will be able to get a wider range of applications, such as thrombolysis.

In this study, we further investigated the feasibility of laser-enhanced HIFU therapy in the in vitro thrombolysis application. The effects of acoustic and laser

parameters (pulsed HIFU wave pulse length, pressure and laser intensity) were assessed. More importantly, the thrombolysis efficiency were measured in both HIFU treatments with and without laser illumination to explore the enhancement of HIFU thrombolysis.

7.2 Materials and Methods

7.2.1 Experimental system

Figure 7.1 System schematic.

The overall experimental arrangement is shown in Figure 7.1. The laser source with a pulse repetition rate of 10 Hz (5-ns pulse width) consists of a pumped Q-switched, Nd:YAG laser and a tunable optical parameter oscillator (OPO) laser (Surelite OPO PLUS, Continuum, Santa Clara, CA). The generated laser beam was formed into a ring-

shaped illumination on a condenser lens and refocused underneath a 5-MHz HIFU transducer (SU-108-013, Sonic Concepts, Bothell, WA) (35 mm focal length), which was mounted on the condenser lens in the center hole. The focal point (-6 dB) of HIFU transducer is $2.61 \times 0.51 \times 0.51$ mm. A 10-MHz focused ultrasonic transducer (V315, Olympus-NDT, Waltham, MA) (37.5 mm focal length; 70% -6-dB fractional bandwidth), which was placed at a 90-degree angle with the HIFU transducer and acted as a passive cavitation detector (PCD), was aligned to be confocal with the HIFU transducer and the laser beam prior to HIFU treatments. The HIFU source waves were generated by a function generator (HP33250A, Agilent Technologies, Santa Clara, CA), and amplified by a 50-dB radio frequency amplifier (350L, ENI Technology, Inc., Rochester, NY), before they were sent to the HIFU transducer through a matching network to induce cavitation in the sample. The PCD signal was received by a pre-amplifier (5072PR; Olympus-NDT, Waltham, MA) and captured by a data acquisition card (GageScope, CS21G8-256MSn Gage, Lockport, IL) in the personal computer. A 10-MHz high-pass filter was used to remove contributions from the HIFU fundamental and second harmonic frequencies in order to ensure that the detected signals were mainly received from broadband acoustic emissions of cavitation. Both the 10-MHz and 5-MHz transducers were immersed in a water tank filled with degassed water during the treatment.

7.2.2 Clot preparation

Whole bovine blood mixed with CaCl_2 in ~6 mm inner diameter tygon tubing, was immersed in a 37 °C water bath for 2 hours and then stored at 4 °C for up to 3 days to generate clots. Before the experiment, the clots cut into roughly cylindrical small pieces

with a diameter of 5 mm and a length of 5 mm were placed in a tygon tubing (6.25 mm ID and 7.81 mm OD). The blood clots have a initial mass weight of 205 ± 41 mg (n=155).

7.2.3 Experiment procedure

All experiments were conducted in a water container filled with degassed water. Each blood clot were cut and weighted before the treatment and then placed in a tygon tubing for exposure under HIFU transducer and laser light. During the sonication, HIFU transducers, PCD detector and laser beams were driven by 3-D translation stages along x, y and z directions. The predetermined speed of the movement along x direction was 0.25 mm/s and the step size for y and z directions were set to 0.5 mm and 1 mm according to the size of the clot and HIFU transducer focal point. After the treatment, the clots were flushed with saline solution on a 400 μ m pore size filter for weighting. The difference between the initial clot weight and the weight on the filter was used to calculate the weight loss, which is thrombolysis efficiency, and expressed by percentage.

7.2.4 Assessment of ultrasound and laser parameters

The experiments were performed in 3 groups. Each group contained only one variable (HIFU pulse length, HIFU pressure or laser fluence) with the other parameter remained same in order to examine the influence of each variable on thrombolysis efficiency. The treatment was repeated 5 times at each variable and performed both with and without laser illumination for comparison. The duty cycle for all treatments was 1:10. The laser wavelength used in this study was 760 nm.

7.3 Results and Discussion

Figure 7.2 Thrombolysis efficiency correlated with HIFU wave pulse length in the treatment with and without laser radiation.

The mean thrombolysis efficiency was plotted as a function of pulse length in Figure 7.2. The HIFU pressure and laser fluence used in this group was 13.2 MPa and 27 mJ/cm², respectively. This laser fluence at 760 nm laser wavelength was slightly higher than the safety limit recommended by American National Standards Institute[129], which is 26.4 mJ/cm². As we can see in the figure, longer pulse length yielded higher thrombolysis efficiency until it tended to reach a saturation stage. With laser, the saturation point (800 μs pulse length) was reached earlier than it in the treatment without laser (1000 μs). In

the rise stage of the curves, the thrombolysis efficiency was greatly enhanced by laser. At the pulse length of 800 μ s, the enhancement was about 53.1%. To further investigate the possible reason of this enhancement, acoustic cavitation signals were detected at each pulse length by the transducer. It is shown that cavitation threshold in the treatments with laser was at 400 μ s pulse length. However, without the laser illumination, the cavitation will not occur until the pulse length reached 1000 μ s. As we know, cavitation has been demonstrated to enhance thrombolysis effect. Therefore, the enhancement of HIFU thrombolysis treatment was due to the laser-induced acoustic cavitation.

Figure 7.3 Thrombolysis efficiency measured under different HIFU pressures with and without laser radiation.

To test the influence of HIFU pressure on thrombolysis efficiency, HIFU pulse length (1000 μ s) and laser fluence (27 mJ/cm^2) were fixed. It is indicated in Figure 7.3 that at 5 and 7 MPa HIFU pressure, the thrombolysis efficiency were only about $21.1 \pm 3.0\%$ and $18.6 \pm 3.9\%$. However, as the HIFU pressure increases, a maximum of $74.2 \pm 2.8\%$ clot weight loss can be reached. Also, treatment with ultrasound alone produced less thrombolysis than it with the presence of laser. In addition, acoustic cavitation can be observed at 7 and 9 MPa with and without laser help. Thus, similarly, it is demonstrated again that the laser illumination has successfully lowered cavitation threshold and therefore enhanced the HIFU thrombolysis efficiency.

Figure 7.4 Thrombolysis efficiency with increasing laser fluence.

The increasing laser effect on thrombolysis effect was also examined as shown in Figure 7.4. The HIFU pressure was determined to be 9.18 MPa and HIFU wave pulse length was 1000 μs in these treatments. Acoustic cavitation threshold was observed at laser fluence of 16 mJ/cm^2 . At laser fluence smaller than 16 mJ/cm^2 , there was low thrombolysis efficiency. However, as the laser fluence increased, a steep increase in thrombolysis efficiency can be seen in the plot, which attributes the success to the laser induced cavitation.

7.4 Conclusion

This study investigated the feasibility of using laser induced cavitation to enhance in vitro HIFU thrombolysis treatment without any addition of thrombolytic agent or microbubbles. Three important ultrasound and laser parameters (HIFU wave pulse length, HIFU pressure, laser fluence) were chosen to test their influence on thrombolysis efficiency. In most case, the larger the pulse length, HIFU pressure and laser fluence, the better the thrombolysis efficiency can be obtained. The optimal parameters were a pulse length of 1000 μs , HIFU pressure of 13 MPa and under 27 mJ/cm^2 laser radiation, at which a maximum thrombolysis efficiency ($74.2 \pm 2.8\%$) were achieved. This in vitro data will help to establish an optimal strategy for laser enhanced HIFU thrombolysis.

In addition, significant enhancement of thrombolysis efficiency was observed with laser illumination. Laser induced cavitation was considered to be a primary factor in the enhancement of HIFU thrombolysis treatment, because it is shown that cavitation threshold was greatly reduced when laser was running concurrently with HIFU treatment.

We have shown in our previous study[139] that laser enhanced HIFU treatment can be used in soft tissue thermal ablation. In this study, the results implied that this technique without any external agent added has successfully shown another potential application in the thrombolysis field. More future work is need to evaluate its in vivo and clinical feasibility and potential risk of injury of vessel wall and surrounding tissue.

Chapter 8 Conclusion

8.1 Summary

The goal of this dissertation is to understand that photoacoustic imaging can be performed to increase the accuracy and efficacy of HIFU treatment. Four main sections were presented in this study. First, our results included the investigation of feasibility of integrated PAI and HIFU system to guide HIFU thermal necrosis both *ex vivo* and *in vivo*. Second, the real time PAI monitoring HIFU was applied for accurate evaluation of thermal ablation outcomes. Third, during PAI monitoring HIFU, a significant enhancement of both temperature elevation and lesion size were found, therefore, laser enhanced HIFU treatment were presented with cavitation detection. Finally, we expanded this laser enhanced technique to thrombolysis application. The results obtained from above four applications form the primary contribution of this dissertation, which is to demonstrate photoacoustic imaging, other than ultrasound imaging and MRI, can not only be used to guide, monitor HIFU treatment, but also improve HIFU treatment by enhancing cavitation effect.

8.2 Findings

According to the obtained results for the four sections, we concluded a set of findings.

In the first section, an integrated PAI and HIFU system was developed and used to treat soft tissue. Based on the successful experience with *ex vivo* experiment, the *in vivo* HIFU ablation on tumors was performed. In the *in vivo* experiment, gold nanorods

was employed as a contrast agent to enhance the target imaging contrast. Two weeks after the treatment, the tumor on the leg area of the BALB/c mouse cannot be observed and the lesion was healed. The outcome of both ex vivo and in vivo PAI guided HIFU ablation is to prove that it is feasible for PAI to be a guidance and evaluation tool for HIFU therapy.

Generally, the transducers used in treatment operate in the 1-10 MHz frequency range, with 2-4 MHz being the most common. However, a HIFU transducer with 5 MHz central frequency was used throughout this work. The reason of choosing 5 MHz is that the HIFU transducer in this study was not only acted as an ultrasound transmitter, but also a photoacoustic signal receiver. Thus, choosing 5 MHz central frequency can allow us to find a balance between transducer sensitivity (energy delivery) and imaging quality (axial resolution).

The second section is to find out a better way to monitor HIFU ablation in soft tissue in real time. Currently, all studies were using temperature change to estimate the tissue necrosis, and the temperature was measured indirectly by using the change of sound speed. However, the drawback is that the sound speed measurement may not be accurate since the tissue property changes during the heating. Thus, the temperature measurement is not a reliable methods for tissue coagulation. In our experiment, a 10 MHz ultrasonic transducer was added to the system for receiving photoacoustic signals between two HIFU burst cycles to eliminate the interference of strong HIFU signals. The results showed that PA amplitude increased during HIFU and finally reached a saturation stage, which was an indication of complete tissue coagulation. The third finding is that

the change in PA amplitude during HIFU is about 3-fold (Fig.9). Therefore, the sensitivity of PA detection using 5-MHz HIFU transducer seems very high.

In the third section, we found that HIFU heating is enhanced when PAI technique is used to monitor HIFU lesion formation. We tested this technique both in ex vivo soft tissue and in vivo mice tissue. The 10 MHz transducer was not used as a photoacoustic signal detector but a passive cavitation detector. It is observed in the ex vivo experiment that a 15 °C temperature difference and a larger lesion volume when laser was running concurrently with HIFU heating. In the in vivo measurement, the cavitation pressure threshold was significantly lowered when laser presented. It seems that the laser illumination is the key for the heating enhancement. The possible reason for the enhancement is due to the decrease of cavitation threshold at a relatively lower HIFU pressure.

Finally, in the fourth section, we tested the laser enhance HIFU therapy in the pulsed HIFU thrombolysis application. There are two outcomes from this section. First, the result helped us establish an optimal strategy for laser enhanced HIFU thrombolysis. Second, the results showed great improvement of thrombolysis efficiency (blood clot weight loss) and laser induced cavitation was considered to be a primary factor, because the cavitation pressure threshold was reduced by laser radiation.

8.3 Suggestions for future work

More efforts are still needed to improve the treatment planning and optimize the parameters to improve predictability for laser enhanced HIFU therapy.

1. The typical lateral size of the HIFU beam focal area is smaller than 1 mm, and usually much smaller than the tumor size. Also, the tumor may distorted unpredictably in their shape during the heating because the change of tissue properties. Thus, a higher imaging quality is needed to accurately profile the tumor for ablation. Moreover, a scheme is necessary in order to enhance the efficacy of HIFU therapy.

2. More experimental results should be obtained and analyzed in order to find out the lesion volumes under different combinations of ultrasound, laser and tissue parameters. This will help us to treat a certain size of tumor more accurately and thus more efficiently.

2. Since HIFU treatment is a very complex process and related to a lot of factors, a theoretical modeling of acoustic and temperature field with amplitude, frequency, and geometry of the HIFU transducer, tissue properties and heat diffusion is need to optimize the parameters of HIFU transducer and treatment protocol.

3. The treatment depth of laser enhanced HIFU therapy is not deep enough for wider applications. Either better laser system or proper treatment strategy should be employed to increase the laser fluence in the targeted area several centimeter inside the soft tissue.

guided high-intensity focused ultrasound. *Applied Physics Letters*. 2011;99(23).

Vita

Huizhong Cui was born in Changchun, Jinlin province, People's Republic of China in 1983. He moved to Tianjin in 1994 with his family when he was in fourth grade in primary school. After finishing high school in 2002, he joined Huazhong University of Science and Technology in Wuhan, Hubei province and got a Bachelor's degree in Mechanical Engineering and Automation in 2006. In the same year, he came back to Tianjin and started to study in Tianjin University of Technology and Education. In December 2008, he received his Master's degree in Mechanical Engineering. In January 2009, he came to University of Kansas in Lawrence, Kansas, United State of America to join Dr. Xinmai Yang's group to start his research on photoacoustic imaging guided high intensity focused ultrasound. After four years study, he earned his Ph.D degree in 2012.
